Abstract

High disparity among avian forelimb and hind limb segments in crown birds relative to non-avialan theropod dinosaurs, potentially driven by the origin of separate forelimb and hind limb locomotor modules, has been linked to the evolution of diverse avian locomotor behaviors. However, this hypothesized relationship has rarely been quantitatively investigated in a phylogenetic framework. We assessed the relationship between the evolution of limb morphology and locomotor behavior by comparing a numerical proxy for locomotor disparity to morphospace sizes derived from a dataset of 1,241 extant species. We then estimated how limb disparity accumulated during the crown avian radiation. Lastly, we tested whether limb segments evolved independently between each limb module using phylogenetically informed regressions. Hind limb disparity accumulated rapidly early in avian evolution, whereas hind limb disparity accumulated later, in more recent divergences. We recovered little support for strong correlations between forelimb and hind limb morphology. We posit that these findings support independent evolution of locomotor modules that enabled the striking morphological and behavioral disparity of extant birds.

Keywords: locomotor modules, morphological disparity, avian macroevolution

Extant birds (Aves) are among the most speciose and ecologically diverse clades of tetrapods. This diversity is reflected in the array of locomotor behaviors birds employ: birds use their wings and legs to fly, walk, run, climb, swim, and dive. Behavioral variation has been linked to a shift in limb function and neural control early in the evolution of birds that resulted in the simultaneous origin of three separate functional units, termed locomotor modules (Gatesy & Dial, 1996). In the evolution of these modules, the forelimb was first co-opted for flight, the hind limb and tail were subsequently decoupled from their shared role in terrestrial locomotion, and then the tail was integrated into the flight apparatus (Gatesy & Dial, 1996). The evolution of these three modules in Avialae is well documented in the fossil record by musculoskeletal evolution in the avialan dinosaur hind limb and tail and shifts in hind limb scaling from non-avialan theropod dinosaurs to crown birds (Allen et al., 2013; Clarke & Middleton, 2008; Clarke et al., 2006; Dececchi & Larsson, 2013; Gatesy, 1991, 2002, Hutchinson, 2001a, 2001b, 2002; Hutchinson & Allen, 2009). Locomotor modularity was hypothesized to have allowed birds to evolve novel locomotor strategies by differentially elaborating individual modules. Specifically, the morphological and functional evolutionary trajectory of each module can be modified in different permutations, enabling a wider array of locomotor behaviors in birds relative to their non-avialan theropod ancestors (Gatesy & Dial, 1996).

Forelimb and hind limb proportions are far more variable in crown birds than in non-avialan theropod dinosaurs (Benson & Choiniere, 2013; Carrano & Sidor, 1999; Gatesy & Middleton, 1997; Middleton & Gatesy, 2000; Mitchell & Makovicky, 2014). One explanation for this pattern is a hypothesized link between limb morphology and ecological traits, including flight capabilities and limb use. However, establishing this relationship has proven challenging, in part, due to the many factors influencing limb morphology, from allometric and phylogenetic factors (Doube et al., 2012; Kilbourne, 2013; Nudds et al., 2013; Stoessel et al., 2013; Wang & Clarke, 2014) to biomechanical factors such as maintaining stability and low energetic costs during movement (Stoessel et al., 2013; Zeffer et al., 2003). Additionally, some locomotor behaviors influence limb morphology more strongly than others, in particular wading or different types of aquatic locomotion (Baumgart et al., 2021; Hinić-Frlog & Motani, 2010; Wang & Clarke, 2014; Zeffer et al., 2003). Thus, broad flight-style categories and aerodynamic variables (e.g., wing loading, aspect ratio) can fail to predict forelimb morphology and wing shape across large phylogenetic samples (e.g., Karoullas & Nudds, 2021; Nudds et al., 2007; Taylor & Thomas, 2014; Wang & Clarke, 2014, 2015). That said, recent multivariate approaches have yielded more compelling results: a combination of multiple morphological characters across the body correctly predicted discretized categories of extant bird ecology (Mitchell & Makovicky, 2014),

and high-density morphometric data showed how limb shape covaries with ecology more strongly than limb size (Orkney et al., 2021). In addition to direct links between limb morphology and ecology, the locomotor modularity hypothesis (Gatesy & Dial, 1996) predicts a positive correlation between variation in limb morphometrics and locomotor disparity that has not yet been evaluated.

Evolutionary dynamics of differential elaboration between locomotor modules is also poorly known. For example: How do limb measurements change when lineages evolve new ways of moving? Do limb modules covary due to selective pressure on whole-organism performance (see Clarke & Middleton, 2008; Heers & Dial, 2015; Orkney et al., 2021)? Older comparisons of limb morphology and locomotor behavior in extant avian clades usually considered a single limb pair or analyzed each limb separately (e.g., Nudds et al., 2013; Stoessel et al., 2013; Wang & Clarke, 2014; Zeffer et al., 2003). Scenarios that can produce covariation between locomotor modules, such as cooperative limb function perpetuated by mutually reinforcing selection or functional tradeoffs due to contrasting selection between individual limb functions, are of particular interest because they channel how locomotor modules can differentially elaborate. Multiple examples of cooperative use of forelimbs and hind limbs, specifically in juveniles that are non-volant, were previously discussed (see Dial, 2003b; Dial et al., 2015; Heers et al., 2014). Cooperative function between limbs, particularly when negotiating 3D terrain, likely played a prominent role in shaping avian limb evolution during and after the origin of flight (Clarke & Middleton, 2008; Dial, 2003b; Heers et al., 2014).

Despite the potential importance of coevolution between locomotor modules in birds, until recently, there have been few quantitative comparisons between the forelimb and hind limb modules across all birds (but see Orkney et al., 2021). Rather, studies have considered morphological differences among different ecological guilds, the effect of flight loss on limb evolution within single clades (Livezey, 1988, 1989, 2003), and comparisons among different locomotor behaviors within a lineage (e.g., Hertel et al., 2015; Miles & Ricklefs, 1984; Miles et al., 1987; Mitchell & Makovicky, 2014; Mitsuo, 1955; Norberg, 1979). Other work has showed that the ratio of forelimb to hind limb muscle mass negatively covaries with ecology between ground dwelling and aerial specialists (Heers & Dial, 2015), inertial properties of the forelimb and hind limb scale differently with body mass and individual limb sizes (Kilbourne, 2013), forelimbs and hind limbs cooperatively interact during takeoff and landing (Provini et al., 2012; Provini et al., 2014), and that island populations tend to possess decreased flight muscle mass and longer legs compared to mainland relatives (Wright et al., 2016). Taken together, these examples show that potential correlations between limbs should be considered when exploring macroevolutionary patterns in avian limb proportions, because selective pressures on the whole organism may affect differential elaboration between modules.

Here, we present an assessment of the evolution of avian forelimb and hind limb segments across a large dataset (N =2,549 measurements for 1,241 species) of crown birds, with increased sampling in previously underrepresented subclades. Specifically, we test the following hypotheses about limb evolution in birds: (a) limb disparity and locomotor behavior disparity are correlated at the major clade level and (b) covariation within hind limb and forelimb modules is stronger than that between modules. We first examine morphospace occupancy for each limb in each major subclade and investigate potential relationships among diversity in locomotor behavior and morphological evolution of limb segments. We predict that larger morphospace sizes will be positively correlated with locomotor disparity. We evaluate whether birds established their forelimb and hind limb morphospaces early in their evolutionary history. Furthermore, we test for potential evolutionary covariation within and among locomotor modules by examining evolutionary rates in limb element lengths and phylogenetically informed covariation of segment lengths between limbs. If modules are evolutionarily linked, we predict similar evolutionary covariation within limbs and between homologous elements (e.g., humerus and femur), whereas weaker covariation between limbs would support differential elaboration between avian locomotor modules.

Methods

Morphometric data set assembly

To investigate the evolution of avian limb morphospace, we obtained 2,549 raw lengths (in mm) of forelimb and hind limb segments (i.e., humerus, radius/ulna, carpometacarpus, femur, tibiotarsus, and tarsometatarsus; see Figure 1) for 1,241 species of extant birds from all major avian subclades, as well as for 4 recently extinct taxa (see Supplementary Methods). Forelimb and hind limb data for 1,121 of these taxa, as well as the 4 extinct species, were taken from previous studies (Gatesy & Middleton, 1997; Hinić-Frlog & Motani, 2010; Middleton & Gatesy, 2000; Mitchell & Makovicky, 2014; Nudds et al., 2013). Data for 120 new extant taxa were added through measurement of museum specimens to supplement underrepresented subclades (e.g., Coraciimorphae N = 30, Aequornithia N = 29, and Galloanseres N = 19 specimens; see Supplementary Methods). Raw measurements for each limb of multiple individuals of the same species were subsequently used in comparative analyses to account for measurement error, and species means were used to test hypotheses of limb evolution (see below). All statistical analyses were carried out in R v. 3.4 (R core team, 2017). Graphics were created using the R package ggplot2 (Wickham, 2009).

Phylogenetic tree construction

We used a supertree of avian taxa (Burleigh et al., 2015) pruned to the taxon set with measurement data to estimate the evolution of limb-proportion disparity-through-time, as well as to test evolutionary covariation between limbs. We employed a modified version of the Burleigh et al. (2015) tree that was scaled to absolute time divergence estimates in millions of years from a recent genome-based avian phylogeny (Jarvis et al., 2014; Riede et al., 2016). We pruned the supertree using the R packages ape v. 3.3 and geiger v. 2.06 to include only taxa that had data from both limb pairs, resulting in a 1140 taxon tree (Harmon et al., 2008; Paradis et al., 2004). We also used another time-calibrated molecular phylogeny (Prum et al., 2015) to test if topology and sampling affected our results, pruning it to a tree comprising 183 taxa. In cases where the original trees included species that were not sampled (6 taxa for Burleigh et al., 2015; 56 taxa for Prum et al., 2015), we replaced those taxa with sampled members of the same genus. For 6 species from the Prum et al. (2015) tree congeneric taxa were not sampled. In these cases

Figure 1. Diagrammatic representation of a bird skeleton indicating measurements for each limb. Total lengths were obtained for the humerus (HUM), radius/ulna (RADULN), and carpometacarpus (CMC) segments for the forelimb, and the femur (FEM), tibiotarsus (TBT), and tarsometatarsus (TMT) segments for the hind limb. Species visualized is the rock dove (*Columba livia*).

we replaced these tips with the next most closely related taxon in our dataset according to current phylogenetic hypotheses (see Alström et al., 2013; Dufort, 2016; Garcia-Ramirez et al., 2014; Moyle, 2004; Ramirez et al., 2013; Xia et al., 2016).

Quantifying avian limb morphospace

To visualize avian hind limb and forelimb morphospace, we took the species averages of log-transformed limb segment lengths. Next, to account for allometric scaling, we computed phylogenetic residuals under a Brownian motion (BM) model of trait evolution for each log-transformed trait regressed on body size. We then calculated relative limb segment lengths as the residuals of a phylogenetic regression on log body mass using the phyl.resid function in phytools (Revell, 2012). For visualization purposes, we conducted separate principal components analyses on residual forelimb (three traits) and hind limb segment lengths three traits) and visualized each morphospace using PC1 and PC2 (we retained these PCs because they accounted for >95% for each limb module; see Figure 2). To quantify clade-specific morphospace sizes, we calculated the volume of an N-dimensional convex hull circumscribing species traits (i.e., residual segment lengths; see above)

using the convhulln function in the R package geometry v. 0.4.5. Although we originally defined 18 clades, convex hulls require at least 3 points for estimating 3-D volumes (for the hind limb, forelimb) and 6 points for 6-D volumes (for the overall limb morphospace). Therefore, we obtained overall limb morphospace volumes for 15 clades and limb-specific volumes for 16 clades. These morphospace volumes were used in understanding clade-specific patterns of morphospace occupancy and in calculating lineage densities, but we did not compare volumes directly in comparative analyses (see *"Testing the locomotor disparity hypothesis"* for details and additional disparity metrics used in analyses). To determine a clade's uniqueness in morphospace, we determined the non-overlapping volume of each clade using the voloverlap function of pavo (Maia et al., 2013).

Quantifying locomotor disparity

To characterize clade-specific locomotor disparity, we coded each clade for the presence or absence of several different locomotor behaviors using life history data in the Handbook of the Birds of the World (del Hoyo et al., 1992-2013). In total, we identified and scored ten unique forelimb-related behaviors and eleven hind limb-related behaviors in each clade (see Supplementary Methods). We then summed the number of behaviors as discrete integer scores of locomotor disparity for each clade. Although birds often perform locomotor behaviors considered outside their typical repertoire, we only included behaviors commonly used by each clade, as determined by descriptions of their life history. Importantly, our approach follows Taylor and Thomas (2014) in coding taxa (i.e., clades) as a mosaic of multiple locomotor behaviors rather than assigning taxa to single locomotor categories (e.g., see Baumgart et al., 2021). Caveats of our mosaic approach include (a) all locomotor behaviors are treated as functionally equivalent (e.g., a clade with hovering and sallying has the same locomotor score as a clade with wing-propelled diving and soaring) and (b) evolutionary variation at the species level may be missed (e.g., if a species loses a locomotor behavior specific to its clade). Yet, given the evolutionary scale of our question (i.e., we want to know whether locomotor disparity is associated with limb morphological disparity at the clade level) and the lack of life history data for several of the species in our dataset (del Hoyo et al., 1992–2013), we feel our approach is warranted.

Testing the locomotor disparity hypothesis

To test our hypothesis that larger morphospace sizes will be associated with greater locomotor disparity, we took a phylomorphospace approach (Sidlauskas, 2008). This is because expansions in morphospace can be caused either by elevated rates of evolution in some clades (i.e., those that utilize a greater number of locomotor modes) or differences in mode of evolution that expand morphospace (e.g., morphological innovations associate with different locomotor behaviors). These two scenarios can be teased apart analytically by analyzing rates of evolution and lineage density, respectively (Benson & Choiniere, 2013; Sidlauskas, 2008). Briefly, we reconstructed ancestral states for each set of trait residuals using fastAnc in phytools (Revell, 2012) and calculated morphological disparity as the sum of Euclidean distances between all adjacent nodes and tips of the phylogeny (Sidlauskas, 2008). We then divided these morphological branch lengths by phylogenetic branch lengths and averaged values for each clade to derive

Figure 2. Avian limb morphospace. Principal component axes representing >95% variation in relative limb element lengths for the forelimb (A) and hind limb (B). Arrows represent PC loadings, with labels corresponding to limb segments (Humerus: HUM; Radius/Ulna: RADULN; Carpometacarpus: CMC; Femur: FEM; Tibiotarsus: TBT; Tarsometatarsus: TMT). Points represent mean values for species colored by clade. Silhouettes represent taxa that occupy unique positions in morphospace.

clade-wise estimates of evolutionary rate. This approach conveniently provides single rate estimates for the fore and hind limb, rather than an 3×3 rate matrix for each, as in a multivariate BM model. To calculate lineage densities, we divided the sum of morphological branch lengths within a clade by its morphospace volume (Sidlauskas, 2008). Since limb disparity calculated as the sum of morphological branch lengths is potentially sensitive to the number of lineages in a clade (Sidlauskas, 2008), we also calculated limb disparity as the mean pairwise Euclidean distances among lineages in morphospace (Foote, 1993), a metric that is independent of sample size. We finally tested for relationships between response variables (morphological disparity, evolutionary rate, lineage density) and locomotor scores using phylogenetic generalized least squares (PGLS) multiple regressions implemented in the R package phylolm (Ho & Ané, 2014).

While our phylomorphospace approach takes into account branch lengths, clade age and species richness could also influence our results. For example, if limb morphology is evolving by a BM process, then we would expect a positive relationship between limb disparity and clade age. Thus, we wanted to account for these covariates in our analyses. We used stepwise multiple regression to determine the best-fitting model based on Akaike information criterion (AIC) scores. For the PGLS analyses, we pruned the Kimball et al. (2019) time-calibrated tree by collapsing the 18 major clades into individual terminals (see ESM for results using the Prum et al. [2015] tree). We natural log-transformed response variables prior to regression and assessed normality of residuals with quantile-quantile plots in R. To assess the effect of potential outliers, we removed influential taxa and re-fit PGLS models in the influ_phylm function of sensiPhy (Paterno et al., 2018).

Understanding the tempo and mode of evolution of avian limb traits

We evaluated whether birds established their morphospace of limb dimensions early in their evolutionary history, compared to expectations under a diffusive, BM model. Following Cooney et al. (2017), we first estimated ancestral states of relative limb segment lengths using fastAnc (Revell, 2012). We then divided the tree into 1-My time bins and, for each bin, calculated disparity as the mean Euclidean distance among lineages present at that time (Foote, 1993). We calculated these disparities for each limb module separately (e.g., among humerus, radius/ulna, and carpometacarpus relative lengths for the forelimb module). To test whether disparities were higher or lower than expected by chance, we simulated multivariate BM evolution 100 times with mvSIM (Clavel et al., 2015) and re-calculated disparity-through-time curves for each simulated dataset. We then determined the 95% confidence interval with the quantile function in R. To compare forelimb and hind limb disparity trends, we determined differences in disparity for each time bin and tested whether this difference fell outside the 95% CI of the difference calculated from trait simulations (see Dryad for R code).

We further tested if evolution in one limb is correlated with evolution in the other by estimating evolutionary rates and covariances among our six residual segment lengths using the ratematrix R package (Caetano & Harmon, 2017). Since these traits are all expected to covary strongly with body size, we also analyzed raw segment lengths with log body mass included (N = 7 traits). To statistically compare rates and covariances, we calculated pairwise differences between them and computed Bayesian P values as the proportion of the posterior sample overlapping zero, using the helper function pMCMC in MCMCglmm (Hadfield, 2010). We adjusted *p* values for multiple tests with the false discovery rate metric with the p.adjust function in R.

Results

Limb morphospace comparisons

Forelimb morphospace was twice as large as hind limb morphospace (0.176 log mm³ vs. 0.061 mm³; Figure 2). Regions of morphospace unique to particular clades comprised a

smaller proportion of total hind limb variation than in the forelimb, as clades overlapped more in hind limb morphospace than in forelimb morphospace (Figure 2). Most clades had larger hind limb than forelimb morphospace volumes (12/16, 75%), with a few notable exceptions: Strisores (nightjars, hummingbirds, and swifts; 0.015 vs. 0.004 log mm³) and Paleognathae (tinamous, "ratites"; 0.044 vs. 0.0006 log mm³; Figure 2). Strisores, Aequornithes, and Paleognathae dominated unique forelimb morphospace (0.055 log mm³; 97.3% of unique volume) due to a combination of shorter humeri (hummingbirds, swifts, treeswifts, and penguins), longer carpometacarpi (hummingbirds, swifts, and treeswifts), and shorter carpometacarpi (ostriches, tinamous, and rheas) relative to all other birds (Figure 2A). Acquornithes (including loons, petrels, penguins, storks, herons, cormorants) occupied the majority of unique hind limb morphospace (0.012 log mm³, 92.7% of unique volume) due to longer tibiotarsi in loons and the some procellariids such as the great shearwater (Puffinus gravis), as well as longer tibiotarsi and shorter tarsometarsi in penguins (Figure 2B).

Locomotor disparity hypothesis

Overall limb disparity (Figure 3A) and hind limb disparity increased significantly with locomotor disparity (Supplementary Figure S3D), whereas forelimb disparity was not significantly related to locomotor disparity (Supplementary Figure S3B) but instead increased significantly with species richness and clade age (Table 1). Evolutionary rates were not significantly related to locomotor disparity for either locomotor module (Figure 3B, Supplementary Figure S3B,E; Table 1). Lineage densities were significantly lower in clades with higher locomotor disparity for both limbs analyzed together (Figure 3C), but the relationship was not significant when limb modules were analyzed individually (Supplementary Figure S3, Table 1). Results were congruent using an alternative disparity metric that is less sensitive to sample size (mean pairwise distance [MPD]), with clade age explaining a significant proportion of variation in forelimb disparity, and species richness and locomotor disparity each explaining a significant proportion of hind limb disparity (Table 1). The relationship between overall limb disparity and locomotor disparity was not significant using the MPD disparity metric, but instead clade age explained a significant proportion of variation in overall limb disparity (Table 1). These results were robust to an alternative phylogeny (Supplementary Table S3) and removal of potential outlier taxa (Supplementary Table S4). Eight clades had both larger hind limb morphospace and higher locomotor scores than the forelimb. Of these, Aequornithes ("waterbirds") had the highest locomotor score in both the forelimb (locomotor score = 6) and hind limb modules (locomotor score = 7; Supplementary Figure S3). Only one clade had both a higher forelimb locomotor score and forelimb morphospace size than in the hind limb: Strisores (forelimb locomotor score = 5, morphospace size = $0.014 \log \text{ mm}^3$; Supplementary Figures S1–S3).

Tempo and mode of avian limb segment evolution

Temporal disparity analyses showed contrasting evolutionary patterns for the accumulation of disparity in the forelimb and hind limb (Figure 4). Forelimb disparity was greater than expected under a BM model early on in avian evolution, whereas hind limb disparity did not differ from the pattern expected under BM (Figure 4). Forelimb and hind limb disparity curves were similar after excluding paleognaths from the analysis (Supplementary Figure S7). Multivariate rate analyses showed significantly stronger covariation within the forelimb than within the hind limb or among limb modules (Figure 5). Evolutionary rates were also higher in forelimb traits than in hind limb traits, with the exception of the tarsometatarsus, which was evolving faster than all other limb traits (Figure 5). Rates of evolution were similar for stylopod elements (humerus and femur). Within limb evolutionary

Figure 3. Correlated evolution of limb disparity and locomotor disparity in birds. (A) raw morphological disparity (sum of morphological branch lengths) increases with locomotor disparity (number of distinct locomotor modes in a clade; p = .049). (B) Evolutionary rates did not covary with locomotor disparity (p = .66). One example of a case where we would expect a positive relationship between these variables is if the evolution of novel locomotor behaviors leads to relaxed selection on limb morphology that translates into greater rates of limb evolution. (C) Lineage density was lower for clades with greater locomotor disparity (p = .03). This is expected if diverse clades partition morphospace through innovations associated with different locomotor (or foraging) modes. Size of points corresponds to log number of species in the clade. Outliers and focal clades labeled. Cartoons illustrate different scenarios, with color of circles representing novel locomotor modes and position of circles corresponding to a particular morphology. Shaded regions are linear model fits for visualization purposes only (see Table 1 for statistical output).

For each model, the most parsimonious set of predictors are presented (significant predictors in bold). Variables were removed in a bidirectional stepwise fashion based on AIC values with phylostep (Ho & Ané, 2014). Partial R^2 values calculated by comparing model with and without that predictor using R2.lik (Ives, 2019). AICc weights show reduced model support (see Supplementary Table S2 for model selection). Results were robust to outliers (i.e., all results for locomotor score that were significant remained significant after running influ_phylm, and vice versa for non-significant results; see Supplementary Table S4). Time-calibrated phylogeny of Kimball et al. (2019) was used in analyses.

covariation was expectedly higher than between limb covariation, with one exception: tarsometatarsus-radius/ulna covariation was similar to femur-tibiotarsus covariation (Figure 5). As expected, all limb measurements were significantly correlated with body mass (Supplementary Figure S5).

Discussion

Forelimb morphospace is objectively larger than hind limb morphospace

Different patterns of morphospace distribution were seen in the forelimb and hind limb of extant birds. Specifically, hind limb morphospace was roughly half the size of forelimb morphospace, but individual clades tended to occupy larger areas and overlapped more (Figure 2; see Supplementary Methods). In contrast, forelimb morphospace showed a larger fraction occupied by single clades (Figure 2). Unique regions of limb morphospace were dominated by taxa that display more specialized locomotor behaviors. For example, the largest areas of unique forelimb morphospace were occupied by taxa known for emphasizing aerial locomotion over terrestrial locomotion, including hummingbirds and swifts (Strisores clade), swallows (Passeriformes clade), and albatrosses (Aequornithes clade). These taxa clustered in three separate regions: these Strisores possess long carpometacarpi and short humeri, swallows show long radii/ulnae and short humeri, and albatross display short carpometacarpi and intermediate humeri and radii/ulnae (Figure 2A). Each of these taxa exemplifies notably different flight styles, namely "hummingbird-style" flight in hummingbirds, continuous flapping in swifts and swallows, and dynamic soaring in albatross (Bruderer et al., 2010; del Hoyo et al., 1992-2013). Unique forelimb space in Strisores and swallows was linked to

maneuverability (Middleton & Gatesy, 2000). For Strisores, this may be due to their unique flight styles and increased area for attachment of the primary remiges (Middleton & Gatesy, 2000; Savile, 1950). In the case of albatrosses, elongate proportions in the humerus may be due to stability required in dynamic soaring (Middleton & Gatesy, 2000).

Flightless paleognaths (ratites such as ostrich and emu) and flightless wing-propelled divers such as penguins and the great auk (Pinguinus impennis) also occupied unique forelimb morphospace, owing to proportionally longer humeri than other taxa. These two areas are not, however, overlapping: flightless paleognaths possess shorter distal wing segments, whereas wing-propelled divers have shorter radii/ulnae (Figure 2A; also see Middleton & Gatesy, 2000; Wang & Clarke, 2014). Shortened distal wing elements are a common feature of flightless taxa, although paleognaths take this trend to an extreme (Livezey, 1988, 1989, 2003; Middleton & Gatesy, 2000). Proportionally shortened intermediate wing elements appear linked to efficient wing-propelled diving in volant and flightless divers (Livezey, 1989; Middleton & Gatesy, 2000). In penguins, the humerus makes up proportionally more of the forelimb than in volant wing-propelled divers, potentially due to flight loss. From a functional perspective, proportionally shorter distal wing elements aid in moving wings through water, a comparatively denser medium than air (Storer, 1960). Waterbirds (clade Aequornithes) were previously shown to occupy a large area of unique forelimb morphospace (Wang & Clarke, 2014). This unique morphospace is reduced in our sample to only include penguins and albatrosses, due to increased taxonomic sampling in Galloanserae (gamebirds), Mirandornithes (grebes and flamingos), Gruiformes (cranes, rails, and allies), Otidimorphae (bustards and cuckoos), and Charadriiformes (shorebirds such as gulls, auks, and coursers).

Figure 4. Accumulation of avian limb disparity over time. Solid lines show limb disparity calculated over different time bins for forelimb (red) and hind limb relative segment lengths (blue), based on the Burleigh et al. (2015) tree topology (N = 1,140 species). The x-axis represents time, starting at the tips of the phylogeny and ending at the root. The y-axis represents mean disparity (pairwise Euclidean distances) calculated in 1-My time bins. Dashed lines represents 95% confidence intervals for null disparity curves estimated by 100 Brownian motion simulations. Segments at the bottom indicate regions of time over which forelimb disparity was significantly higher than hind limb disparity (see Methods for details).

In the hind limb, Aequornithes dominated unique areas of morphospace due to long tibiotarsi (in loons) and long tibiotarsi paired with short tarsometatarsi (in penguins). Grebes, a convergent clade of specialist foot-propelled divers, approached loon morphospace but do not possess such elongate tibotarsi. Although not included in these analyses, extinct flightless foot-propelled diving hesperornithiform birds from the Cretaceous occupied unique hind limb morphospace typified by an extremely long tibiotarsus (Gatesy & Middleton, 1997). More elongate tibiotarsi support extensive distal hind limb musculature in foot-propelled diving loons, grebes, and Hesperornithiformes, enabling efficient aquatic propulsion (Clifton et al., 2018). Penguins also occupy a unique region of hind limb morphospace characterized by an extremely abbreviated tarsometatarsus (Gatesy & Middleton, 1997). Other taxa approach this space, consisting of taxa that primarily locomote using their wings, including fregatids, some hummingbirds and swifts, some parrots, and kingfishers (Gatesy & Middleton, 1997). In contrast to penguins which are accomplished walkers, most of these taxa excluding some parrots rarely locomote on land, and some are nearly incapable of walking (Le Maho & Dewasmes, 1984). As with foot-propelled divers and elongate tibiotarsi, the evolution of more abbreviate tarsometatarsi in wing-propelled divers and

taxa that emphasize perching over walking indicates that certain locomotor behaviors might have consistent proportional signals, but may not be detected in analyses that examine all of avian diversity. Terrestrial and wading taxa show a similar effect: flamingos are waders that occupy unique morphospace due to elongate tarsometatarsi and short femora. Wading long-legged taxa such as stilts and avocets, the saddle-billed stork (*Ephippiorhynchus senegale*), as well as more terrestrial species including the secretary bird (*Sagittarius serpentarius*) and pratincoles, also approach this unique region of morphospace. Going forward, examining intra-clade evolution following the origin of novel locomotor behaviors might clarify this pattern, as well as other potential associations between limb disparity and behavior.

Limb morphospace and the acquisition of novel locomotor modes

We found that locomotor disparity and limb disparity are positively correlated across birds for both the combined (Figure 3A) and hind limb data sets (Supplementary Figure S3D, Table 1). However, this relationship was not found for the forelimb. This pattern could result from either of two evolutionary processes: (a) elevated rates of morphological evolution in clades with more locomotor modes or

Figure 5. Evolutionary rates and covariation of relative limb segments in birds. Evolutionary rate matrix for three relative forelimb segment lengths: humerus (HUM), radius/ulna (RADULN), and carpometacarpus (CMC), and three hind limb segments: femur (FEM), tibiotarsus (TBT), and tarsometatarsus (TMT). Ellipses in lower off-diagonals display recovered evolutionary relationships among traits using ratematrix. Histograms of Brownian evolutionary rates (σ^2) are shown on the diagonals (black histograms), and histograms of covariances are shown on the upper off-diagonals (gray histograms). Statistical comparisons were made between evolutionary rates and covariances by calculating Bayesian *p* values in MCMCglmm (Hadfield, 2010), accounting for multiple tests with false discovery rate *p* value adjustment. Small circles indicate significance of comparisons–any two rate (or covariance) histograms sharing similarly colored circles are not significantly different from each other (e.g., relative tarsometatarsus length is evolving significantly faster than femur length, and tibiotarsus-tarsometatarsus covariance is not significantly different from covariation between the radius/ulna and carpometacarpus). Note: only among-rate and among-covariance comparison can be made, as this is how we conducted significance testing.

(b) acquisition of new locomotor modes enables exploration of novel regions of limb morphospace (e.g., Figure 2B). Phylogenetic regression analyses suggest that rates of limb evolution are similar across clades with simple and complex locomotor behaviors (Figure 3B, Supplementary Figure S3B,E, Table 1; all p > .05). However, we found that clades with more locomotor behaviors are less closely packed in morphospace, showing significantly lower lineage densities in overall limb morphospace (p < .01; Figure 3C) and significantly higher mean pairwise distances in hind himb morphospace (p = .03; Table 1). Together, these findings suggest that the evolution of new locomotor modes has allowed lineages to exploit new regions of hind limb morphospace (e.g., Baumgart et al., 2021; Falk et al., 2021; Orkney et al., 2021). By contrast, clade differences in forelimb disparity are primarily a function of clade age and species diversity (Table 1). These findings lend support to the hypothesis that locomotor modularity enabled more behavioral options for living birds. The recovered positive relationship between hind limb morphological disparity and locomotor disparity is intuitive, but interesting in light of the fact that consistent associations between limb morphometrics and ecology in birds have largely proved elusive (Shatkovska & Ghazali, 2020), outside of some wading and diving taxa (Hinic-Frlog & Motani, 2010; Stoessel et al., 2013; Wang & Clarke, 2014; Zeffer et al., 2003). This may be due, in part, to differences in how morphological disparity relates to behavioral disparity between the forelimb and hind limb modules (Table 1), or that some previous studies assigned taxa to single ecological (e.g., arboreal, swimming, terrestrial) or flight style categories (e.g., continuous flapper, dynamic soarer; e.g., Baumgart et al., 2021). Instead, our approach codes taxa as a mosaic of multiple locomotor characteristics rather than singular classifications (see Taylor and Thomas [2014] for another example of this approach). Continued use of multivariate methods will continue to be a valuable strategy for testing hypothesized ecomorphological patterns (e.g., Mitchell & Makovicky, 2014, Orkney et al., 2021) and studying morphological integration, a grand challenge in comparative vertebrate morphology (Danos et al., 2022). One caveat of our approach of counting clade-specific locomotor behaviors is that it treats all locomotor behaviors as functionally equivalent; for example, clades that used hovering and soaring would have the same locomotor score as a clade that uses wing propelled diving and sallying. Future analyses comparing limb morphological variation and locomotor behavior disparity could interrogate this relationship at the species-level in a phylogenetic context (e.g., using Markov models and multivariate discrete variables).

The multifunctional nature of avian limbs may be a major obstacle in recovering consistent associations between limb morphology and locomotor behavior (see Stoessel et al., 2013). Anatomical structure must address multiple functional demands, which can prevent the evolution of an optimum morphology for a particular function (Wainwright et al., 2005). A role for multifunctionality and behavioral plasticity should also be considered when investigating linkages between avian morphology and locomotor behavior (see Diogo [2017] for a broader discussion). Phylogenetically informed investigations of multiple character systems that unite locomotor behavior, ontogeny, and morphology, as well as studies of avian locomotor biomechanics and community-level ecomorphological trends in extant and extinct birds, are all needed to overcome these problems (e.g., Danos et al., 2022; Dial, 2003a; Heers et al., 2011, 2014; Mitchell & Makovicky, 2014; Orkney et al., 2021; Ricklefs & Travis, 1980; Smith & Clarke, 2014; Xu et al., 2014).

Early gains of forelimb disparity in birds

Limb disparity accumulated differently between limbs during the evolution of birds (Figure 4). Analyses of temporal trends in limb disparity supported a scenario wherein the majority of forelimb disparity evolved quickly among major avian clades early on in the avian radiation (Figure 4). This pattern was driven primarily by divergence in forelimb morphology among flightless paleognath lineages (e.g., ostrich, emu, and rhea; see Figure 2A, Supplementary Figure S7). These results are consistent with patterns recovered from smaller datasets and narrower taxonomic focus or sampling that suggest changes in the hand occur early in avian evolution (Nebreda et al., 2020) and that forelimb morphology does not often change significantly with the origin of novel flight styles (Supplementary Figure S3, Table 1; also see Wang & Clarke, 2014, 2015). Yet, our results contrast with evolutionary patterns in limb morphospace previously reported from Mesozoic birds: stem avialans show similar forelimb disparity as non-volant theropods, whereas hind limb disparity diversified in stem pygostylians (Benson & Choiniere, 2013). High phylogenetic signal across all traits (Supplementary Table S1) is consistent with previous findings that phylogenetic effects must be taken into account when investigating the relationship between limb morphology and ecological or locomotor signals (e.g., Baumgart et al., 2021; Nudds et al., 2007; Orkney et al., 2021; Stoessel et al., 2013; Wang & Clarke, 2014).

Support for independent avian limb modules

We find support for stronger limb integration within forelimb and hind limb modules than between them (Figure 5). This result is consistent with a recent study that used a high-density morphometric dataset but in fewer taxa (Orkney et al., 2021). This partial limb module decoupling is consistent with the observed differences in disparity accumulation over time for the different limb modules (Figure 4). Interestingly, stylopod-autopod (humerus-carpometacarpus, femur-tarsometatarsus) and zeugopod-autopod covariances (radius/ulna-carpometacarpus, tibiotarsus-tarsometatarsus) were similar for each limb (Figure 5). This suggests potential developmental constraints, as limbs are homologous and involve similar genes/expression profiles (Young & Hallgrimsson, 2005). Stylopod-zeugopod covariances were significantly different across limbs (humerus-radius/ ulna, femur-tibiotarsus), as relative segment lengths in the forelimb were more strongly integrated (Figure 5). Forelimb traits showed significantly higher evolutionary rates than most hind limb traits, with the exception of the tarsometatarsus (Figure 5). In the hind limb, the stylopod and zeugopod elements (femur and tibiotarsus) evolved at the same rate, whereas for the forelimb the zeugopod (radius/ulna) evolved significantly faster than the humerus (Figure 5) and at the same rate as the autopods (carpometacarpals). The fastest evolving limb element was the hind limb autopod (tarsometatarsus). This different in rates between autopods might be reflective of stronger stabilizing selection on wing/ forelimb morphology due to flight requirements, whereas the tarsometatarsus is able to evolve more freely possibly due to relaxed selection (Lahti et al., 2009). Taken together, our finding of weaker evolutionary covariation among forelimb and hind limb modules than within them is consistent with recent work using geometric morphometrics (Orkney et al., 2021) and work by previous authors who found no support for morphological integration between serial limb homologues (e.g., humerus and femur) in a sample of 174 specimens of 7 bird species (Bell et al., 2011). These results support the hypothesis put forward by Gatesy & Dial (1996) that limb modularity may have enabled differential evolutionary elaboration among modules, facilitating morphological and locomotor disparity in birds.

Conclusion

Extant avian clades that display higher disparity in locomotor behaviors show greater limb disparity. Furthermore, evolutionary trends in disparity differed between the forelimb and hind limb. Forelimb disparity evolved rapidly among clades early in avian evolution, whereas hind limb disparity diversified within rather than among clades. Phylogenetic effects are a significant factor in explaining the variation observed in avian limb morphology; comparative study of avian limbs should incorporate phylogeny. Avian forelimbs and hind limbs show different evolutionary rates, and evolutionary changes in one locomotor module do not closely correspond to predictable changes in the other module when considered across birds as a whole. These findings, in concert, support the hypothesis that the origin of separate locomotor modules aided the evolution of avian locomotor disparity, and that morphological disparity accumulated differently between modules. Although locomotor modularity may be linked to the evolution of diverse morphologies and, by extension, locomotor behaviors in birds, comparative examinations of morphological evolution following the origin of specific novel locomotor behaviors (e.g., wing-propelled diving, scansoriality) are necessary to understand how limb form and function evolved across different avian lineages.

Supplementary material

Supplementary material is available online at *Evolution* (https://academic.oup.com/evolut/qpac039)

Data availability

Supplementary files consisting of (1) a CSV file containing all primary morphological data; (2 and 3) two NEXUS files of the edited phylogenetic trees used in this study; and (4) an R-markdown file outlining all analyses run for the manuscript. CSV files containing primary data and R code used in this study are available on Dryad (https://doi.org/10.5061/dryad.f4qrfj70k).

Author contributions

C.M.E., J.V.P., and J.A.C. jointly conceived the study. C.M.E. and J.V.P. assembled the dataset. J.V.P., J.A.C., and C.M.E. designed the analyses. J.V.P. carried out the analyses with aid from C.M.E. J.V.P., J.A.C., and C.M.E. jointly drafted and edited the manuscript. J.V.P., J.A.C., and C.M.E. jointly designed the figures. J.V.P. produced the figures.

Funding statement

We thank the National Science Foundation (DEB 0949897 "Collaborative Research: Wings to Flippers-Phylogenetics, Character Acquisition, and Feather Biomechanics in the Evolution of Wing-Propelled Diving" awarded to J.A.C.; GRFP DGE 1110007 awarded to J.V.P.; EP 2112468 awarded to C.M.E.) and the Jackson School of Geosciences for financial support.

Conflict of interest: The authors declare no conflicts of interest.

Acknowledgments

We thank Chris Sagebiel (Jackson School of Geosciences Vertebrate Paleontology Laboratory), Kimball Garrett (Natural History Museum of Los Angeles County), Ben Marks (Field Museum of Natural History), Gary Voelker (Biodiversity Research and Teaching Collections, Texas A&M University), and Christopher Milensky (Smithsonian National Museum of Natural. History) for access to museum collections and specimens. We also thank Jessica Valdes, Leah Hudson, and Jennifer Millard for help with collecting data. John Mitchell, Kevin Middleton, and Sanja Hinić-Frlog generously provided their datasets on avian limb measurements. We also thank Lauren English, Chris Torres, Zhiheng Li, Nick Crouch, Sarah Davis, James Hall, Jenny Le, Paul Viola, Jessica Valdes, Hector Garza, and Rebecca Van Houten for supplying helpful feedback. This work was completed in partial fulfillment of J.V.P.'s PhD degree from The University of Texas at Austin.
